TRENDS in Plant Science

How trees use water — water transportation

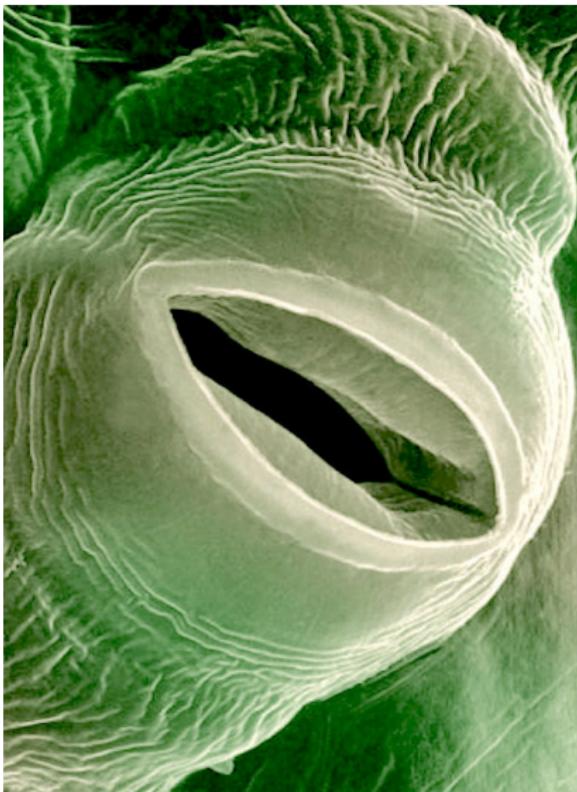

How trees use water — gas exchange

How could tree optimize water usage

- Via the root water absorption;
- Via the water transportation pathway;
- Via the gas exchange.

How do stoma regulate the pore size?

Feedback control

- VPD;
- Soil water potential;

Active control

- ABA;
- Light.

How stoma regulates pore size

← stoma →

Higher [CO₂]
Lower Humidity
Drier Soil

Save water

Lower [CO₂]
Higher Humidity
Wetter Soil

Gain carbon

How to model stomatal control?

Summarize?

“Guess”?

Empirical Model

Ball, Woodrow and Berry (1987)

$$g_{sw} = k \cdot A \cdot \frac{h_s}{c_s} \quad (1)$$

Ball, Berry and Leuning

$$G_H = G_0 + \frac{a \cdot A}{(C_a - \Gamma)(1 + D_L/D_0)} \quad (2)$$

G_0 , a , and D_0 are fitted parameters.

Photosynthesis Optimization Model

Cowan and Farquhar (1977)

$$\frac{\delta E}{\delta A} = \lambda \quad (3)$$

The disadvantage is the definition of λ , and there is no details of what λ should be.

(Dis-)Advantages

Advantages

- Small time complexity;
- Easy to model;

Disadvantages

- No response to $[CO_2]$ or soil moisture;
- Rely on dataset to obtain the empirical parameters;
- Lack interface to physiological traits;

We need better models!

Why do trees regulate stomata?

To reproduce?

ABSTRACT

Stomatal regulation presumably evolved to optimize CO₂ for H₂O exchange in response to changing conditions. If the optimization criterion can be readily measured or calculated, then stomatal responses can be efficiently modelled without recourse to empirical models or underlying mechanism. Previous efforts have been challenged by the lack of a transparent index for the cost of losing water. Yet it is accepted that stomata control water loss to avoid excessive loss of hydraulic conductance from cavitation and soil drying. Proximity to hydraulic failure and desiccation can represent the cost of water loss. If at any given instant, the stomatal aperture adjusts to maximize the instantaneous difference between photosynthetic gain and hydraulic cost, then a model can predict the trajectory of stomatal responses to changes in environment across time. Results of this optimization model are consistent with the widely used Ball-Berry-Leuning empirical model ($r^2 > 0.99$) across a wide

1987). The trade-off has seemingly resulted in tight coordination between capacity to supply and transpire water (hydraulic conductance, k , and diffusive conductance to water vapour, G_w) and the maximum capacity for photosynthesis (carboxylation rate, V_{max} , and electron transport rate, J_{max} ; Brodribb *et al.* 2002). If the fulcrum on which this trade-off balances could be identified, it would greatly simplify the difficult problem of predicting how plant gas exchange responds to environmental cues (Prentice *et al.* 2014). In this paper, we describe such a balancing point, explain how it can be readily quantified from measurable plant traits and processes, and evaluate the resulting patterns in stomatal regulation of gas exchange and xylem pressure.

The utility of a stomatal optimization framework has long been recognized, but uncertainty in the optimization criteria and its relation to true fitness costs and benefits has limited its potential for understanding and modelling stomatal behaviour, particularly in response to drying soil. A long-standing theme

How does the model perform?

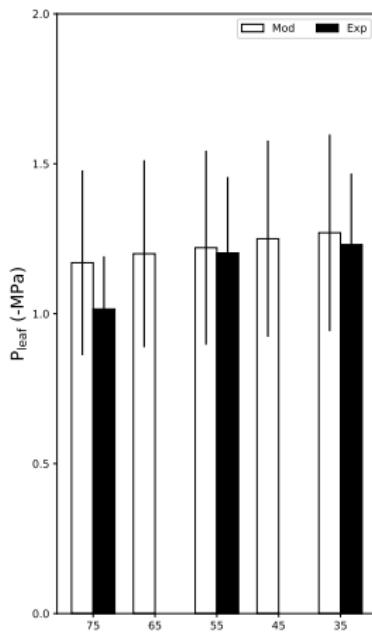

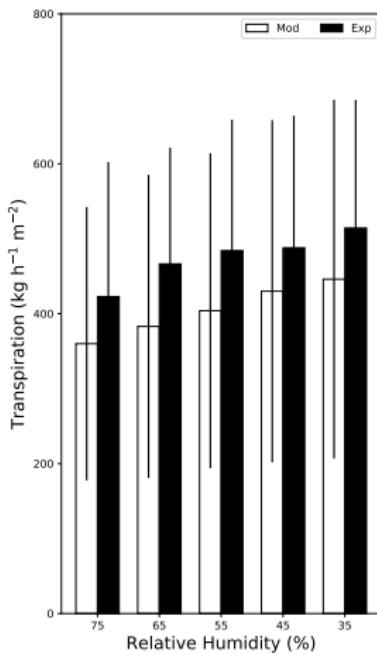

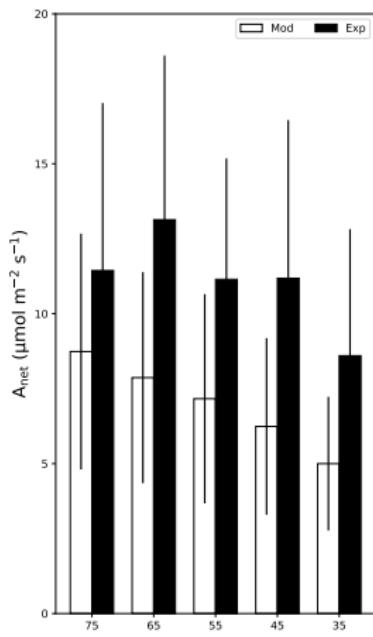

Test the model in growth chamber

Why growth chamber?

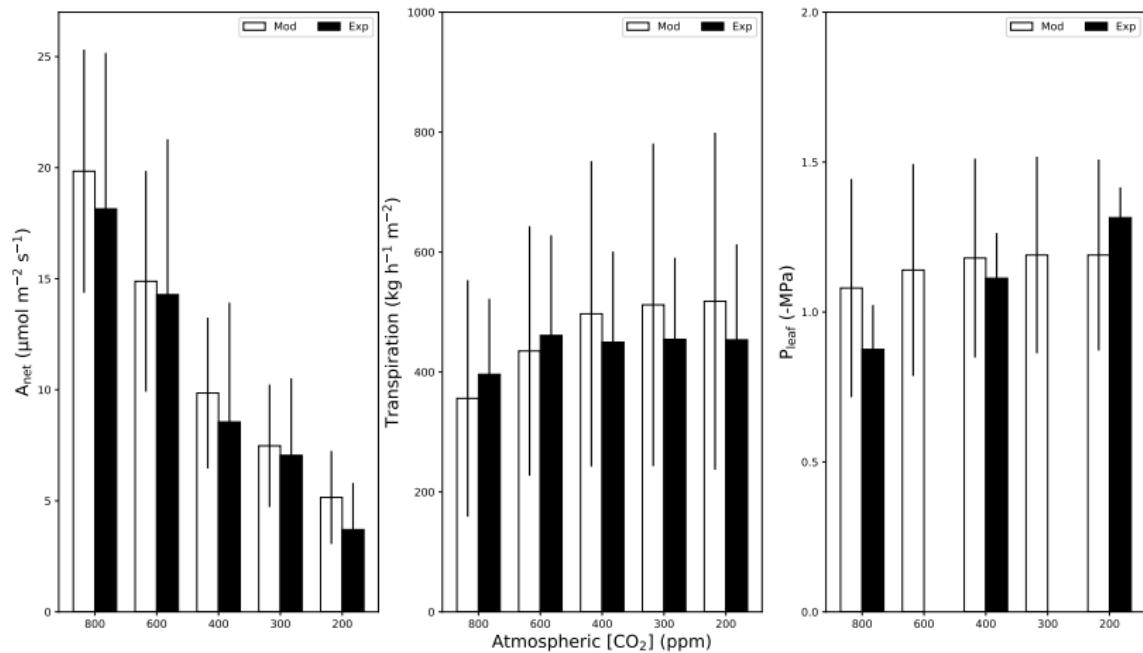

- Stable environment;
- The responses are in plant-level.
